Myths about Historians

Elliott Middleton, Senior Product Manager, Schneider Electric

Executive summary

Relational databases are ideal for many applications, but are not the best solution for time-series data. High throughput systems are not the same as process historians. Relational Database systems are not suitable for everything. While Microsoft SQL Server or Oracle databases are capable of storing timeseries data, there are some very significant problems that should be considered when contemplating their use for process history and industrial applications. This white paper discusses the real reasons why a process historian is superior for plant information acquisition and retrieval when compared to a relational database system.

Introduction

Relational databases are ideal for many applications, but are not the best solution for time-series data. Historian applications have been around a long time and through the years various fallacies and 'myths' have developed and perpetuate without substance or evidence. This paper will discuss the merits and shortfalls of relational databases as well as uncover and challenge these myths in the context of specialized process historian applications. This paper will also present some basics of historian applications, explain some important considerations for an objective evaluation of historian solutions, and properly set expectations for the value a historian can bring.

High throughput systems are not the same as process historians. While examples can be found of the New York Stock Exchange trading systems and other high-throughput applications which use relational databases, it can not be implied from these examples that Relational Database systems are suitable for everything. While Microsoft SQL Server or Oracle databases are capable of storing time-series data, there are some very significant problems that should be considered when contemplating their use for process history and industrial applications.

Myth #1:

Storage is so cheaply that efficiency does not matter

It is common to dramatically underestimate how much data a typical process actually generates. A modest 5,000 tag historian which logs data every second, generates 157 billion distinct values per year. Even when stored efficiently in 8 bytes per value, storage requirements would be around 1 terabyte per year. In some tests when comparing SQL Server storage requirements for timeseries data and necessary indices with those of Wonderware Historian the difference was 50:1. Even though storage prices are falling, 50 terabytes of data a year is still a lot. It should also be recognized that it is not merely a matter of having enough disk space to hold that much data; it is frequently a requirement that historical data be robustly protected, which multiplies the amount of storage required for backups or disk mirroring. Some industries impose mandatory regulatory obligations to maintain several years of data, which further magnify the overall storage requirement.

Myth #2:

Relational databases are fast enough

As hardware price performance has improved, relational databases have benefited. However, relational databases are designed to protect referential integrity around "transactions" that may update multiple table values in unison, which adds significant overhead. For example, on highend hardware (running 64 Itanium processors) SQL Server 2008 established a world record 1126 transactions per second. Granted such transactions are not the same as those required for a historian, but even such high-end hardware would be taxed to store 5,000 values per second if each value was a transaction. This means a front-end buffering application must collect the data and stream numerous values into the database as a single transaction. Other databases without full transactional support, such as MySQL's freeware MyISAM storage engine, can support higher throughputs, but still require a front-end buffer to achieve adequate throughput for all but the tiniest historian applications.

Of course, the reason to store data in the first place is so that it is available to retrieve later. Naturally, that makes retrieval performance quite important, too. Particularly in general-purpose solutions like a relational database, it is possible to organize data so that it is either efficient to store (higher throughput) or efficient to retrieve (fast retrieval), but not both. Efficient retrieval of timeseries data from a general purpose database requires use of a "clustered index," something not available, for example, in the higher-throughput MyISAM storage engine.

In contrast, purpose-built storage engines designed specifically for time-series data leverage the knowledge of how data is collected and consumed to store it efficiently for both—this would not be possible if the data were more generalized.

Myth #3:	Using a relational database as a historian is a new revelation
	There are frequently new ideas about how to apply existing technology—3M Post-It [®] notes were a famous application of an existing not-so-sticky adhesive. However, companies have attempted using a simple relational database schema as a replacement for purpose-built time-series storage for over a decade. In spite of this "new idea" of using a relational database, the market for dedicated historian solutions has continued to grow significantly.
Myth #4:	You can only use SQL to query data in relational databases
	Though relational databases have many advantages over alternative technologies, what catapulted them to prominence was the power of SQL. SQL standardized and fundamentally changed how users can extract value from their data from being a complex programming exercise to being a relatively simple and flexible language to describe the data of interest.
	Fortunately, it is very practical to adapt SQL to non-relational data stores and gain the tremendous benefits and power of SQL without some of the inherent limitations of a relational database.
Myth #5:	There is nothing special about time-series data
	With all the power of SQL to query data, some may claim that relational databases are just as good at retrieving timeseries data as they are for transactional data. It is certainly true that SQL gives great flexibility, but it is based on some fundamental assumptions that do not apply to time-series data: (a) there is no inherent order in the data records (in fact, time-series data is ordered by time), (b) all the data is explicitly stored (in fact, most historian data only represents samples from a continuum of the real data), all data is of equal significance.
	These two differences are significant. For example, if an instrument reports a value time stamped at "7:59:58.603" and a user queries a relational database for the value at "8:00:00.000," no data will be returned since there is no records stored for precisely that time—the database does not recognize that time is a continuum. Similarly, if a temperature was "21°C" and two-minutes later was "23°C," it has no inherent ability to infer that halfway between these samples the temperature was approximately "22°C."
	In historian applications, steady-state operations are rarely most significant. The only way for a client application to find exceptions is to query all of the data for a measurement, which can place a heavy load on the overall system: server, network and client. In contrast, historians generally have means of filtering out insignificant data (based on comparing sequential records) to radically reduce the volume of data that must be delivered to client applications.
Myth #6:	Managing time-series data in a relational database is trivial
	Relational databases are designed to accumulate massive amounts of data. However, as the amount of data grows, so do query execution times, the size of backups, and numerous other routine operations. To alleviate this performance problem of ever-growing tables, database administrators must routinely purge data from the database. In any database that protects transactional integrity, this purge operation must suspend normal database updates—that is a

problem for historian applications running 24/7/365. To even make the purge operation tolerable

requires minimizing the amount of data maintained in the database.

In the event purged data is needed later (for example, in response to an audit or some regulatory demands), restoring the data is non-trivial. The generally recommended practice is to restore a full database backup that included the needed data either to a separate system dedicated for this purpose, or to take your production system offline and use it. This is even more problematic if the required data is not available within a single database backup—for example, if you only maintain the last 30 days of data in the online database and the audit requires 90 days of data, you must either manually merge all the data into a single database, have three systems, each with an isolated 30-day window, or examine each backup serially.

True historians, on the other hand, are designed to both handle the rapid growth in data and to provide simple means of taking subsets of the data offline and online.

Myth #7:

The only options are fully relational or fully proprietary historian solutions

While it is true that most historian solutions either use fully proprietary technology to address the inherent limitations of relational database or fully leverage relational database to reduce their own engineering costs, Wonderware Historian actually delivers the best of both worlds. It relies on a solid relational schema for managing all the relatively static configuration data, but extends the native transactional storage engine and query processor of Microsoft[®] SQL Server with proprietary extensions to address their limitations for time-series data.

Building on Microsoft SQL Server delivers a solution that is easier to secure and manage than fully proprietary solutions, but without compromising on the fundamental capabilities required in a historian.

Myth #8:

There is nothing special about industrial applications

True historians provide facilities for dealing with the demanding, real-world realities of industrial applications that are outside the realm of pure relational databases. How do you intend to make use of the data? Do you need to convert rates into quantities for reporting? If so, that is quite complex with a SQL query. Is your instrumentation and data collection 100 percent reliable, or do you sometimes have to "make do" with data that includes instrument errors? While general-purpose databases can certainly store data, they are not designed to incorporate notions of "data quality" into calculations and are not able to simply perform routine time-series calculations such an integral calculation that are commonly needed.

Myth #9:

Relational database applications are not historians

A "historian" addresses several related functions: continuously collecting real-time data, storing noteworthy subsets of that data, and providing a means of extracting meaningful information from that data. Whereas "historian" describes an application, "relational database" names a technology. Though there are certainly some significant challenges in using a relational database technology for time-series data, just because an application uses one does not mean it is not a historian—it can still be a historian, just a fairly basic one. Rather than focusing on the underlying technology choices (relational databases or proprietary files), focus on the functionality needed—that requires an understanding of the overall application and involves much more than simply storing data.

Myth #10:

All data is equal in importance and validity

To a relational database, a stored value is precisely that, a value, and is always assumed to be valid—if it is not, it is up to someone to correct it. In collecting millions of samples from thousands of data points from around a process, it is inevitable that some information is incorrect or missing. There may be issues with measurement equipment where values are out of range, communications was lost, or the data was simply erroneous.

In a plant historian, a stored data point not only has an associated value and time stamp, it also has an indication of the data quality. Storing a data point from an instrument, outside of the instrument's normal operating range, for example, will cause a specific series of quality indicators to be stored with the value. These indicators are not simply separate columns in the database, but an inherent property of the sample. They can be retrieved, included in calculations and used to alert operations or engineering personnel to a potential anomaly.

When summarizing the values (for example, calculating an average temperature over the last hour), a historian must be able to reflect this data quality in calculation results, optionally filter out suspect data, and be able to extrapolate when data is missing or deemed invalid. If these real-world aberrations are not handled correctly, resulting reports, business system integration, and decision making will be incorrectly skewed. Relational databases alone do not provide these capabilities.

Myth #11: Storing data in a relational database makes it easy to query

Although support for SQL queries is one of the huge benefits of using a relational database, that doesn't necessarily mean a particular database design is easy to query via SQL—some designs are even so convoluted that they cannot effectively use manually-created queries and must, instead, rely on complex, programmatically generated queries. This can make sense from the perspective of managing the storage and from the standpoint of portability, but it largely neutralizes all the inherent advantage of using a relational database.

Myth #12: Storing data in a relational database makes it integrated

Putting two Excel spreadsheet files into the same folder does not make them "integrated" in any sense, even though they might both include production data. Similarly, taking information from an ERP (enterprise resource planning) system and historian and storing both in a relational database does not make it "integrated". Certainly having all that data in a common technology is the requisite first step, but it is only that and often it is by far the simplest.

Myth #13:

Using a relational database is cheaper than a purpose-built historian

Before you assume you cannot afford a serious historian solution, make sure you understand your real needs and explore the options—you might be very pleasantly surprised, even based only on the license costs. When you factor in the lower ownership costs and value of a solution adapted to your real needs, the purpose-built solution will likely be a lot cheaper.

Myth #14:

Only large-scale continuous processes need a historian

The original commercial historian systems began in the 1980s in oil refining, paper mills and other continuous processes since these were the only industries that could justify the cost of minicomputers required to run them. With the rapid adoption of Windows NT in the 1990s, the cost of the computers dropped significantly and opened the door for lower priced solutions developed specifically for the new platform, such as Wonderware[®] IndustrialSQL Server (now, "Wonderware Historian"). These new solutions quickly demonstrated their cost effectiveness outside of the traditionally DCS-oriented continuous process industries.

Conclusion

This white paper discussed several reasons why a process historian is superior for plant information acquisition and retrieval when compared to a relational database system. However, this does not mean that commercial software has no place in an industrial environment. Today, process information is needed both outside of the plant environment and inside the business systems section of an enterprise. And, there is no better way to provide this interface between the plant data and the enterprise systems than a commercially accepted, standard interface. Wonderware Historian can integrate a commercially available product (Microsoft SQL Server) with an open, standard query interface (SQL) to provide open access to plant historical data. This interface can easily be used by the IT department for reporting or integrating into the ERP systems.

Wonderware Historian offers all the capabilities discussed within this paper and more. Trusted and in use in over 25,000 installations worldwide, Wonderware Historian empowers plant operations and enterprise business users alike, delivering the right information to the right person, and leaves database management where it belongs, in the enterprise IT department and not on the plant floor.

About the author

Elliott Middleton has over 25 years of experience with industrial software, primarily with process historians, business system integration and operations intelligence applications. As a product manager, he is responsible for setting the direction for the Schneider Electric software information solutions, including the Wonderware Historian, Historian Client (aka ActiveFactory), and Wonderware Information Server web solution. Working with customers, business partners, and the Invensys development and support teams, Elliott works to identify market problems, define product requirements and prioritize enhancements. Prior to joining Invensys in 2001, he held similar positions at AspenTech and IndX. He holds a Bachelor of Science degree in Computer Science from Baylor University.
